

Why the E_C -only inverse model produces claw > cross designs

A. One E_C target = a whole LINE of "perfect" designs
(loss is identical everywhere on each colored line)

B. E_C locks cross_length exactly, barely sees claw_length
(claw sensitivity in $1/E_C$ fit: 0.1% of cross sensitivity)

C. The old targets were locked to E_C , not extra geometry info
 $\text{corr}(f_q, E_C) = 0.992$, $\text{corr}(\alpha, E_C) = -1.000$

D. A claw-indifferent model fails most at high E_C
(high E_C = short cross, so most claw values overshoot it)
